Abstract

J. Campos and W. Foster. 2012. Effects of contracts and work relationships on salaries and income distribution of workers in the Chilean agriculture sector, 1996 and 2006. *Cien. Inv. Agr.* 39(1): 5-17. During the past thirty years the Chilean economy generally and agriculture specifically have grown considerably, raising both per capita GDP and observed real wages of salaried workers. There has been, however, a concern about the country's persistent unequal distribution of income. Among the possible factors associated with income inequality is the relatively infrequent use of contracts in seasonal and occasional work, both strongly present in agriculture. Based on Chilean household surveys (CASEN) for 1996 and 2006, impacts of contracts and work relationships (permanent, seasonal, etc.) on salaries, and their possible contributions to inequality, were measured, accounting for schooling, ethnicity, work experience, geographic zones, and other variables correlated with salaries. Separate hourly-wage equations for men and women were estimated. *Ceteris paribus*, employees with contracts earn more than those without, and those in a permanent work relationship earn more than those seasonally employed. The negative effects of not having a contract and being in a non-permanent work relationship are greater for women. Schooling is the single most important factor in explaining unequal salaries; however, the contribution of schooling to salary improvement has not changed considerably over time. Contracts and work relationship are important in explaining salary inequality, especially in the case of women.

Key words: Agriculture, labor, gender, income distribution, inequality, work contract, work relationship.

Introduction

Over the last 30 years Chile has experienced economic growth, political stability and increasing integration into world markets. Per capita GDP has doubled, poverty rates have decreased. Chile's unequal distribution of income is noteworthy, and

measured levels of inequality have remained empirically stable over time (Solimano and Torche, 2008, Contreras *et al.*, 2001, Valdés, 1999). Of the many factors that might contribute to income inequality, various characteristics of labor markets have been hypothesized, notably the informality of contracts and the fluidity and impermanency of work relations. The period 1990-2006 was characterized by a rapidly evolving labor market in response to changing patterns of production among sectors

competing for workers of different skill levels. In the case of agriculture, as the composition of production continued shifting from traditional to export-oriented crops, work relationships other than “permanent” (mainly seasonal) increased over time (Amuedo-Dorantes, 2005). As elsewhere, agriculture behaves differently than the rest of the Chilean economy, due to its link with biological cycles and products associated with highly seasonal activities. About 60% of Chilean rural households that depend on agriculture earn the bulk of their incomes from salaried work (the remainder are smaller-farm self-employed or larger-farm employers). Salaried-work households in agriculture show higher poverty rates than the self-employed and those in urban areas (Valdés and Foster, 2009). The participation of these workers in total agricultural earned income in the sector increased from 37% to 52% in the period under review, and it has been the only group that increased in number, rising 21.5% between 1990 and 2006 (Valdés *et al.*, 2008).

As seen in Table 1, the number of female agricultural employees increased between 1996 and 2006 by 65%, while men recorded a 6.3% rise. The male/female ratio is a simple indicator of the composition of employees from a gender perspective; its decrease reflects that the development of agricultural activities, particularly the growth of the agro-export model, which has led to an increase in labor demand satisfied by a greater supply of women entering the labor market (Table 1) (1996 and 2006 surveys CASEN, MIDEPLAN, 1996 and 2006, respectively).

This present study focuses on salaried workers, particularly on their wages and the degree of inequality that characterizes the distribution of hourly earnings of these employees. The objectives of this research are two-fold: a) to determine the impact of the existence of different contracts and working relationships on hourly earnings of employees in the agricultural sector, controlling for characteristics such as education, ethnicity, work experience, and others; and b) to determine

the contribution of these variables to the dispersion of the distribution of hourly wages and the resulting income inequality shown over time. The analysis also emphasizes differences associated with gender.

Table 1. Chilean salaried workers in the Economy and Agriculture Sector in Chile: 1996-2006 (Age 16-65).

Economy	1996	2006	Growth Rate 1996/2006
Men	2,463,136	2,906,083	17%
Women	1,406,534	1,909,727	36%
M/W Ratio	1.8	1.5	
Agriculture			
Men	423,133	450,198	6.3%
Women	82,068	135,499	65%
M/W Ratio	5.2	3.3

Materials and methods

This research uses the National Socioeconomic Characterization Survey (CASEN), of Ministerio de Planificación de Chile (MIDEPLAN) for the years between 1996 and 2006, available from the institution's website (<http://www.mideplan.cl/casen>). For purposes of this investigation, an employee is defined as an individual between 16 and 65 years old who claims to be engaged in a relationship of subordination or dependence with an employer; an agriculture worker is employed in a business, industry or service which is active in the agriculture sector of the economy (Ministry of Planning, 2006).

Income determination and the correction equation for selection bias

The analysis focuses on participants in the labor market; observations are drawn from a self-selecting subset of the population between 16 and 65. The methodology used to correct the selection bias corresponds to the two-stage method of Heckman (1979). The income of employees is analyzed using a standard semi-log (*log-lin*) re-

gression (Mincer, 1974). The econometric method allowed quantifying the marginal effect or impact of a contract (or lack of it) on income levels, as well as identifying how work relationships affect salaries. In addition, several variables have been added to characterize sub-groups of employees. Summary statistics are shown in Table 2.

Selection-bias correction was performed after the application of a standard probit model of the probability of observing a person working or employed. The sample from the CASEN survey corresponds to the individuals belonging to the active labor force in agriculture, both employed and unemployed, in the age range 16-65. The objective is to obtain an indicator that would show the marginal propensity of individuals to be observed as a salaried employee. This indicator is included in the earnings equations and is known as the Inverse Mills Ratio (IMR). Observed and selected individuals correspond to a dichotomous variable, T_i , that equals 1 when the i -th individual declares to be an employee with an hourly wage. In any other case, $T_i = 0$. The probability of being employed is a function of observed characteristics:

$$P(T_i = 1|W_i) = \Phi(W_{it}) \quad (1)$$

where W_i is a vector of observed characteristics of individuals and Y is a vector of coefficients common across individuals in a given year. The IMR (λ_{it}) is calculated as:

$$\lambda_{it} = \frac{\hat{\phi}_{it}(\alpha_{it} z / \psi_{it})}{\hat{\Phi}_{it}(\alpha_{it} z / \psi_{it})} \quad (2)$$

where: $\hat{\phi}_{it}$ corresponds to the estimated function of density probability, and $\hat{\Phi}_{it}$ corresponds to the estimated function of cumulative distribution for each group of employees tested. The functional form to determine the impact of this and all other selected variables on salary are as follows:

$$\ln Y_{it} = \varphi(e_{it}, e_{it}^2 \exp_{it}, V_{it}, \lambda_{it}) + \varepsilon_t \quad (3)$$

where: $i = [1, n]$, n is the number of individuals observed (salaried employees) and $t = 1996$ and 2006 . Y represents the income per hour, e schooling (in years, which enters quadratically to account for possible diminishing returns), exp indicates the work experience (in years). V is a vector that contains the other explanatory variables: the existence of an employment contract, specific work relationship (see below), marital status, ethnicity, occupation, region, urban-to-rural surface area in the worker's municipality (as an indicator of rurality), number of workers in the firm employing the person, and the indicator of selection bias, λ_{it} , IRM explained above. Schooling is defined in this way considering the nonlinearity of the effect on income. All other variables are dichotomous. The income used is the logarithm of hourly earnings expressed in Chilean pesos of November 2008, using the average annual CPI as a deflator.

Decomposition of inequality of labor income

With respect to labor income inequality, the main question is how to use the information contained in the income equations to identify the contributions of each of the explanatory variables to the dispersion of income.

The methodology detailed below is based on Shorrocks (1982). Fields and Yoo (2000) and Amuedo-Dorantes (2005) are interesting applications of this method. To summarize, the decomposition of wage income inequality separates the contribution of the j -th explanatory variable, Z_j , relative to the total variance in a given year. The share, s_j , of the total (estimated) population variance of wages can be rewritten in terms of the sample correlation coefficient between (log) hourly wage and the explanatory variable, scaled by the regression coefficient, a_j :

$$s_j(\ln Y) = \frac{\text{cov}[a_j Z_j, \ln Y]}{\sigma^2(\ln Y)} = \frac{a_j * \sigma(Z_j) * \text{cor}[Z_j, \ln Y]}{\sigma(\ln Y)} \quad (4)$$

where $\sum_j s_j(\ln Y) = 100\%$

All variables are dummies with years of schooling like exception. In the case of dummies variables, the average indicates the proportion in the respective population of the characteristic represented by the variable.

Note that the residual error's contribution to inequality is interpreted as the share of the dependent variable's variance left unexplained by the model proposed.

evaluated using the years 1996 and 2006. The total change from a given inequality measure is the sum of weighted changes of the index:

Changes in income inequality

Fields and Yoo (2000) show how to evaluate the change over time in the contribution of the j -th explanatory variable to income inequality of any arbitrary inequality index. For purposes of this study, the Gini index and the variance of log hourly earnings were used to measure inequality. Changes in the inequality index are

In summary, the detailed breakdown of the inequality in equation (4) allows one to quantify the contribution to hourly wage variance between 1996 and 2006 of contracts and different work relationships. Given the change in income inequality, equation (6) is used to measure how much of the change in inequality across workers' wages between 1996 and 2006 is attributable to changes in the number workers with contracts as well as to with the various work relationships.

$$I(.)_{2006} - I(.)_{1996} = \sum_j [s_{j,2006} * I(.)_{2006} - s_{j,1996} * I(.)_{1996}] \quad (5)$$

$$\text{and, } \Pi_j(I(.)) = \sum_j \left(\frac{[s_{j,2006} * I(.)_{2006} - s_{j,1996} * I(.)_{1996}]}{[I(.)_{2006} - I(.)_{1996}]} \right) \quad (6)$$

where, $\sum_j \Pi_j(I(.)) = 100\%$

Descriptive analysis

Contracts and work relationships, 1996 and 2006.

Table 3 presents the percentages of employees “with contract” and “with no contract” in agriculture, differentiated by gender and observed in the years under study. In the year 1996 both genders had about 58% of employees with contract, while in the year 2006, women reached a level of contract employment greater than their male counterparts: 70% versus 67%.

Table 3. Incidence of Contracts among male and female employees in Chilean agriculture: 1990-2006. (Age 16-65).

Employee	Year	
	1996	2006
Men		
With Work Contract	58.35	67.89
No Work Contract	38.30	27.24
No information	3.35	4.87
Women		
With Work Contract	58.72	70.83
No Work Contract	37.64	24.29
No information	3.64	4.88

Source: Own from CASEN 1996 and 2006.

With respect to work relationships in agriculture, Table 4 shows the percentages of each, differentiated by sex. Men in a “Permanent” working relationship represented 56% of employees in 1996, declining to almost 52% in 2006. In women, these levels were almost half of that observed in men, with levels close to 24% in 1996 and almost 25% in 2006. In contrast, women reached close to 70% for “seasonal” relationships, while men did not exceed 40%. Gender differentiation is observed within same working relationship, as the case of “seasonal”, where men are outnumbered by about 30 percentage points by women. One explanation for higher levels of female seasonal workers is related to their high participation in seasonal activities related to fruit. Table 5 shows a greater concentration of women in regions dominated by fruit growing, that is, between regions IV and VII of the country.

Table 4. Incidence of different types of work relations among male and female employees working in the Chilean agriculture: 1996-2006 (Age 16-65).

Work Relation	Year	
	1996	2006
Men		
Permanent	56.4	51.98
Seasonal	37.24	39.86
Fixed-term	2.12	2.39
Specific Tasks	3.94	5.6
Others relations	0.3	0.17
Women		
Permanent	23.7	24.84
Seasonal	69.72	68.99
Fixed-term	3.5	2.07
Specific Tasks	2.74	3.77
Others relations	0.34	0.33

Source: Own from CASEN 1996 and 2006.

The dominance of the “Permanent” relationship in men, approximately 30 percentage points more than women, may be due to the activities of this sex in agriculture, many of which would require their permanent presence during the year. For example, work management and maintenance of farm infrastructure, care and management of livestock, among others are found primarily in the south of the country, between regions VIII and X, where extensive farming predominates (Table 5).

Work relationships (Permanent, Specific Task, Fixed Term, Seasonal, or Other) have much to do with the seasonality of production and related activities. A sustainable agricultural enterprise requires ways to mobilize a workforce of variable size at critical times and tasks, and in some cases to employ at least a base level of permanent workers (Collins and Krippner, 1999). The use of permanent workers in agricultural activities has been studied in the literature from around the world, including aspects such as lower-cost supervision (Hart, 1986) due to the existence of tasks that require judgement, discretion and care,

Source: Own from CASEN 1996 and 2006.

impact on wages only for men in 1996, while in 2006, it is negative for both sexes, but the effect is greater for women. The negative impact on wage of no contract reached levels of 21.9% for males, and about 27% for females. Table 8 shows these marginal effects expressed in monetary amounts and the average monthly salary received according to the factors used in this study. Having no contract compared to having a contract in 2006, would result in a decrease in the average monthly salary of \$31,000 and \$33,000 (Chilean pesos) in men and women, respectively, economically significant effects considering that the average monthly agricultural wages for 2006 are \$142,000 and \$123,000 for men and women with contracts.

Turning to work relationships, the “temporary” condition, in the case of men, is associated with a reduced income of about 11% in 1996 and 9% in 2006. Table 8 shows that the reduced amount that a temporary employee received, *ceteris paribus*, was approximately \$30,000 and \$20,000 in 1996 and 2006, respectively. Note that the average monthly wage observed for those with a “permanent” relationship is \$252,000 and \$200,000 in 1996 and 2006.

There are also negative impacts for women with a “seasonal” compared to a “permanent” relationship, although this effect decreased from 17.6% lower wage in 1996 to 3.9% in 2006 (Table 7). This is important because this seasonal agricultural labor group is where women are disproportionately represented (Table 4). The lower impact for the year 1996 as compared to men is possibly due to the type of seasonal labor performed by women. Higher levels of productivity for women in seasonal work would reduce the negative effects of this relationship compared to that permanent employment.

Contributions to inequality

Table 9 shows the contribution of each explanatory variable to wage inequality in each year under study and in both sexes. In the case of men, the

Permanent work relation, no married, no ethnicity, less than five years of potential work experience, service-related occupations, XIII Region, small firms and rural zones are used as reference categories. *denotes statistical significance at the 1% level, **indicates statistical significance at the 5% level, and ***represents statistical significance at the 10% level.

most important variable in both years is schooling. In women, schooling is important only in 2006. In 2006 the contributions to inequality of not having a contract are 4.9% and 5.2% for men and women, respectively. In 1996, the contribution is much less, 1.5% for men, and zero for women. There is a notable change in the importance of contracts for women between 1996 and 2006: from a negligible impact, the effect of having no contract is the second most important following schooling. The impact of “no contract” represents a one-sixth of the total contribution explained by the variables included (5.2 percentage points out of an R^2 of 33%).

Work relationships, except for “seasonal”, do not contribute to wage inequality. But the relationship

“seasonal” in the case of men did contribute to approximately 1.6% of the inequality measure. For women, however, the contribution of “seasonal” fell from a relatively high contribution of 3.1% in 1996 to 0.7% in 2006. The observed decrease of the contribution of “seasonal” in the case of women correlates with the growth in the importance of seasonal work among women. As a characteristic of workers becomes more widespread its relative contribution to observed income differences in any one year declines, although in terms of comparisons between years there is a more equal distribution of income.

The contributions of contracts and work relationships to changes in earnings inequality in Chilean agriculture: 1996 and 2006

This section turns to the contributions of contract

Table 8. Average monthly earning's effects of contract and work relations in the Chilean agriculture (Chilean Pesos of November 2008). Work contract and permanent work relation are reference categories.

Men	1996	2006
No work contract (Compared to having contract)	-19,139	-31,333
Specific Task (Compared to having a permanent work relation)	23,256	-10,235
Fixed Term (Compared to having a permanent work relation)	-23,762	-17,058
Seasonal (Compared to having a permanent work relation)	-30,081	-20,670
Other relation (Compared to having a permanent work relation)	-96,058	-9,432
Average Monthly Earnings With Work Contract	173,987	142,424
Average Monthly Earnings of Permanent Work Relation	252,783	200,677
Women		
No work contract (Compared to having contract)	0	-33,316
Specific Task (Compared to having a permanent work relation)	-62,123	-12,761
Fixed Term (Compared to having a permanent work relation))	47,098	-4,712
Seasonal (Compared to having a permanent work relation)	-29,880	-8,442
Other relation (Compared to having a permanent work relation)	35,788	23,755
Average Monthly Earnings With Work Contract	158,525	123,391
Average Monthly Earnings of Permanent Work Relation	168,812	196,319

(or lack thereof) and work relationships to *changes* in the two measures of earnings inequality between 1996 and 2006. The Gini index and the log variance of hourly wages both yield similar results. To facilitate the discussion here, the Gini results are used. First note that the contributions to changes presented in Table 9 are contributions to *reductions* in total income inequality, as seen in Table 6. The contribution of “no contract” to the fall in the inequality indices is negative in the case of both sexes (using the Gini index, for men –5% and for women –8%). The change in the distribution of employment contracts across workers between 1996 and 2006 (Table 3) contributed, *ceteris paribus*, to increasing wage inequality. The “seasonal” condition contributed to the reduction of inequality, with 1.3% for men and 6.8% for women. These contributions to changes in the inequality index should be considered in the light of the total *explained* changes to the indices. The joint contribution of the explanatory variables included in the analysis to the reduction in the Gini index of inequality is 35% for men and 14% for women. Therefore, in the case of females the contribution to the decline in wage inequality due to the growth in the rate of contracts accounts for 57% of the total explained decline.

Discussion

The wage equations allow an assessment of the marginal impacts of the variables “no contract” and work relationships on the hourly earnings of agricultural employees in Chile for 1996 and 2006. The regression analysis corrected for possible selection bias due to censoring of the sample. The regression coefficients permit estimating the contributions of the explanatory variables to inequality indices in each year and to changes in the indices between 1996 and 2006. For both genders the impact on wages and inequality measures of having no contract is negative. Notably the impacts of the work relationship indicators depend on gender, demonstrating the usefulness of differentiating the analysis by men and women.

Not having a contract is notably negatively correlated with women’s wages.

This study provides empirical evidence to complement previous descriptive works on Chilean agricultural employees, including primarily seasonally-employed females, (e.g., Fernandez, 2007). The amounts of forgone monthly income due to informality or non-existence of a contract are economically significant, especially in the case of workers at the lower end of the income distribution. Although not specifically addressed in this study, the results suggest a link between contract status and the type of work relationship and the poverty status of a worker. It is true that the incidence of poverty fell during the period 1996 and 2006, when the proportion of workers under contract increased. The evidence of this study is suggestive, but further research would aid in understanding the possible interrelationship between poverty, work formality, and seasonal work.

Employees who work on a permanent basis enjoy higher wages than those working seasonally or occasionally. For men the negative impact on wages of having a non-permanent work relationship was observed for both 1996 and 2006; interestingly, for women, however, the negative impact of a seasonal work on wages was reduced. Future research would be required to explain in detail the type and nature of activities done by employees of both genders, with an emphasis on how women might have benefited more than men over time when it comes to relationships other than “permanent”. Possibly this effect is due the link between the intermittent labor supply and the seasonality of demand by agricultural producers. A variable supply of female labor (for tempoary, short-term work) in sync with seasonal, demand for labor for harvest and sorting reduces the marginal effects of seasonal work on wage, possibly due to the demand curve shifting out at the same time that higher-marginal-product female workers are returning to the labor market during summer months.

Regarding the distribution of income across workers of different characteristics, contracts and work relationships contribute significantly to inequality in agriculture. Notably, in the case of women workers in the agricultural sector in 2006, the distribution of the “no-contract” characteristic contributed to wage inequality to a degree slightly lower than the contribution of schooling. Fernández (2007) notes the growing demand for contracts by female seasonal workers, suggesting that these employees associate contracts with higher wages.

With regard to the observed changes in measures of inequality between 1996 and 2006 for both sexes, changes in the distribution of contracts across the work force helps explain the reduction in wage inequality, especially for women. With respect to work relationships other than permanent, changes to the distribution of the characteristic “seasonal” work also contributed to reducing the inequality indices, especially in women. Thus, this type of work relationship, associated with a greater flexibility in labor management, applies to individuals of similar marginal products, and whose incomes, therefore, are also similar.

The result show that the lack of an employment contract, at least during in the years analyzed, is negatively correlated with the wages of employees. With respect to work relationships, “permanent” workers receive higher salaries than seasonal or temporary. This last result is particularly relevant for agriculture, and even more so for women workers in the type of activities that predominate in Chile. The research shows that the changes in the distribution of contracts and work relationships contributed to the reduction in inequality measures. It is important to note that in agriculture the ability to explain the wage variation across workers appears low, as shown by the R^2 coefficients. But among the explanatory variables the distribution of schooling remains the main contributor to wage inequality across workers, and changes to this distribution has led to a reduction in inequality from 1996 to 2006.

Resumen

J. Campos y W. Foster. 2012. Efectos del contrato y relación de trabajo sobre el salario y distribución del ingreso en la agricultura de Chile en los años 1990 y 2006. Cien. Inv. Agr. 39(1): 5-17. Durante los últimos treinta años la economía chilena se ha transformado. El crecimiento económico ha sido destacado, aumentando el PIB per cápita y los salarios reales. Por supuesto, la actividad agrícola no ha estado ajena a ello. Sin embargo, existe preocupación sobre la alta desigualdad del ingreso en Chile y su aparente persistencia. La informalidad asociada a la falta de un contrato de trabajo y la proliferación de relaciones de trabajo estacionales u ocasionales, podrían ser señalados como posibles causas que expliquen los niveles de desigualdad, más aún en la Agricultura, donde la informalidad laboral es relevante. A partir de la información contenida en la Encuesta de Caracterización Socioeconómica (CASEN) de los años 1996 y 2006, se establecen los impactos marginales de los contratos y relaciones de trabajo sobre el salario y sus respectivas contribuciones a la desigualdad, controlándose factores como escolaridad, etnia, experiencia laboral, zona geográfica, etc. Se establece que, *ceteris paribus*, los individuos que tienen un contrato de trabajo obtienen ingresos superiores que sus contrapartes que no los poseen, así también, aquellos con una relación de trabajo permanente, respecto de relaciones temporales o por obra. Los impactos negativos son superiores en las

mujeres. La principal contribución a la desigualdad la realiza la escolaridad, aunque a través del tiempo esta variable no ha mejorado el ingreso de los asalariados. Los contratos y relaciones de trabajo son importantes en la explicación de la desigualdad, siendo más relevante en el caso de las mujeres, donde la falta de un contrato de trabajo no contribuyó a reducir la desigualdad, más bien, amplía las brechas salariales.

Palabras clave: Contratos, relaciones de trabajo, asalariados, agricultura, género, desigualdad, distribución del ingreso.
