ABSTRACT

In the present work the synthesis, thermal analysis and structural characterization of Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O are described in order to obtain mixed oxides with technological properties. The starting materials and the decomposition products were characterized by IR spectroscopy, powder X-ray diffraction (XRPD) and scanning electron microscopy (SEM). The crystal structure of Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O has been refined by Rietveld analysis using X-ray powder diffraction data. It crystallizes in the monoclinic system with space group $P2_1/m$ and the cell unit parameters are $a = 10.975(2)$ Å, $b = 7.628(1)$ Å, $c = 8.569(1)$ Å and $\beta = 98.8375(9)^\circ$. Pb$_4$Fe$_9$O$_{15}$ has been obtained by a simple method, the thermal decomposition of Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O at 700 °C in air. Pb$_4$Fe$_9$O$_{15}$ crystallizes in the tetragonal system with cell unit parameters $a = b = 7.80$ Å, $c = 15.82$ Å. PbO is also obtained.

Keywords: Thermal decomposition, Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O, Pb$_4$Fe$_9$O$_{15}$, crystal structure, low temperature synthesis.

INTRODUCTION

The synthesis of mixed oxides, particularly those of the brownmillerite, perovskites and related oxides from the decomposition of inorganic coordination compounds allows to lower the synthesis temperature down to the range 600 – 900 °C (well below the usual temperatures used in the conventional ceramic methods) and to obtain more homogeneous and finely divided powders.

ABO$_x$ perovskite type oxides (0 £ $x$ £ 0.5, A = Lanthanide or alkaline earth, B$^+$ = transition metal) have a great technological interest due to their electrical, magnetic and catalytic properties. They have been extensively used as catalyst in redox reactions, as in the reduction of nitrogen oxides and SO$_x$ and the elimination of atmospheric pollution. In the specific case of A = lanthanum, its oxides are particular suitable for applications as a material for sensors, for the detection of vapors and gases due to the high instability of Fe (IV). When $x = 0.5$ all the iron is in oxidation state 3+ and a brownmillerite type compound is formed.

ABO$_x$ perovskites containing an easily polarizable A cation with a sterically active lone electron pair (Bi$^{3+}$, Pb$^{2+}$) and mostly covalent bonding to oxygen and a magnetically active transition metal B cation are attracting considerable attention nowadays due to expectations of finding new multiferric materials. Multiferroics are materials that are (anti) ferromagnetically ordered, being at the same time in a ferroelectric state. The coupling between the electric and magnetic polarization, i.e., the magnetoelastic effect, imparts great value to such materials for practical applications due to the possibility to controlling the magnetic polarization by an electric field and vice versa.

Pb$_4$Fe$_9$O$_{15}$ is expected to be an anion deficient perovskite of the brownmillerite type. However, its structure has not yet been determined because it has a large variety of crystallographic shear.

In this paper we propose the synthesis of Pb$_4$Fe$_9$O$_{15}$ obtained by a very simple method, the thermal oxidative decomposition of Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O at low temperature. The decomposition process was followed by IR spectroscopy, thermogravimetric analysis (TGA), differential thermal analysis (DTA), laboratory X - ray powder diffraction (XRPD) and scanning electron microscopy (SEM).

EXPERIMENTAL

Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O was prepared by mixing equal volumes of 0.1 M K$_2$[Fe(CN)$_5$]$_3$ and 0.2 M Pb(NO$_3$)$_2$ solutions and stirred for two hours. The white precipitate formed was separated by filtration and washed several times with distilled water and finally stored in a dry box with silica gel.

The thermal decomposition behavior of the complex was studied by thermogravimetric and differential thermal analysis (TGA/DTA). TGA and DTA were performed in a Termogravimetric and Differential Thermal Analyzer Shimadzu TGA/DTA-50 at 5 °C/min under flowing air.

Based in TGA results, the sample was heated in air flow in a furnace at different temperatures for 6 hours in order to obtain Pb$_4$Fe$_9$O$_{15}$. IR spectra were recorded with a FTIR Perkin Elmer 1600 in the transmission mode using KBr pellets.

Laboratory powder XRD pattern for the samples was taken in a Philips PW1710 diffractometer, with CuKα radiation ($\lambda = 1.5418$ Å) at 20° and 90° in 2θ, steps of 0.02°. The structure refinement of Pb$_4$Fe$_9$O$_{15}$.4H$_2$O was performed by Rietveld Method using the FULLPROF program with laboratory powder XRD data, in the space group $P2_1/m$.

The size and morphology of the particles were determined by scanning electron microscopy (SEM) with a JEOL JSM 35 CF.

RESULTS AND DISCUSSION

3.1 Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O

3.1.1 IR spectra

In order to characterize the complex and their thermal decomposition products, IR spectra were recorded in transmission mode. Fig.1 shows the IR spectra for the complex Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O. The IR spectra of hexacyanometallates are composed of three vibrations within the octahedral unit M(CN)$_6$: v(CN), 6 (MCN) and v(MC); and those motions from crystal water, v(OH) and 4(HOH), when it is present. For Pb$_2$[Fe(CN)$_5$]$_3$.4H$_2$O, the v(CN) stretching band is observed at 2041 cm$^{-1}$. For the bending vibrations of water at least three bands are well resolved. The highest frequency band in the δ (HOH) vibrations region, at 1646 cm$^{-1}$, corresponds to the weakly bonded waters, the intermediate one at 1619 cm$^{-1}$ also belongs to coordinated water molecules but with a weaker coordination bond and the band at 1597 cm$^{-1}$ belongs to those water molecules with the stronger interaction with the metal$^{[7]}$. In the ν(OH) vibrations region at 3500 cm$^{-1}$ four bands are observed that corresponds to coordinated water molecules.
3.1.2 Thermogravimetric (TGA) and differential thermal analysis (DTA) data

TGA and DTA data for Pb₂[Fe(CN)₆].4H₂O are shown in Fig. 2 and 3. Three main steps are observed in TGA for the decomposition process in air. The first one ends at 98 ºC, with a mass loss of 10.05 %, due to the dehydration process to obtain the anhidrous complex (theoretical value 10.31 %). This corresponds to an endothermic process observed in DTA at 87 ºC. The second step in TGA finishes at 385 ºC approximately and it has a mass loss of 14.23 %. This mass loss was attributed to liberation of CN groups that in DTA corresponds to a very exothermic peak at 373 ºC. At temperatures above 500 ºC the mass loss remained constant. The total mass loss was 24.28 %, which agrees with the theoretical loss (24.64 %) calculated for the formation of Pb₂Fe₂O₅ and PbO.

The corresponding chemical reaction (partial) could be represented as:

\[
2 \text{Pb}_2[\text{Fe(CN)}_6].4\text{H}_2\text{O} \rightarrow \text{Pb}_2\text{Fe}_2\text{O}_5 + 2 \text{PbO} + \text{volatile products}
\]

We will not speculate about the decomposition mechanism because this is not the objective of this paper.

3.2 Mixed oxides obtained by heat treatment of Pb₂[Fe(CN)₆].4H₂O at different temperatures

3.2.1 IR spectra

IR spectra obtained of the samples heated at different temperatures are shown in Fig. 5. The ν(CN) stretching band disappeared when the complex was heated to 500 ºC, and bands attributable to carbonate groups in the 1100-1500 cm⁻¹ region began to appear. When the complex was heated to 650 ºC, the bands corresponding to carbonate groups disappeared and only a strong band for the stretching M-O typical of the oxides was observed at 561 cm⁻¹. This situation did not change at the temperatures higher than 650 ºC.

The broad band observed in the 3100-3700 cm⁻¹ range in all the samples is attributed to surface-adsorbed -OH species.

The presence of carbonates on the samples is attributed to their exposure
to ambient air at room temperature after cooling. This is in agreement with the studies of Traversa et al. in the sense that the surface of particles obtained by thermal decomposition of some hexacyanoferrates are very active to chemisorption of CO\textsubscript{2} and the consequent carbonate formation on the surface\textsuperscript{18,19}.

**Figure 5.** IR spectra for Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5} obtained by thermal decomposition in air of Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O for 6 hours at different temperatures.

3.2.2 Powder XRD data

The XRPD profiles of the decomposition products of Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O at different temperatures are shown in the Fig. 6. When the complex was decomposed at 500 °C, some peaks attributed to Fe\textsubscript{2}O\textsubscript{3} and PbO\textsuperscript{21} are observed. When the complex was decomposed at temperatures higher 650 °C, the XRPD analysis showed the pattern corresponding to Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5}\textsuperscript{22}, which crystallizes in the Tetragonal system with a = b = 7.80 Å, c = 15.82 Å and PbO\textsuperscript{21} which crystallizes in the orthorrombic crystal system, space group Pbcm, cell parameters a= 5.8760 Å, b= 5.4760 Å and c= 4.7430 Å. Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5} oxide was detected together with PbO because the ratio Pb:Fe in the precursor complex was 2:1.

**Figure 6.** XRPD profiles of the decomposition products of Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O at different temperatures.

3.2.3 Scanning Electron Microscopy (SEM)

Figure 7 shows the SEM photographs of Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O and the decomposition product obtained in air at 700 °C. For Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O the average particle size is approximately 3 μm (Fig. 7a). The size and well defined shapes of the crystals are similar to lanthanum hexacyanoferrates\textsuperscript{19}. After decomposition at 700 °C, the size of the crystals have reduced at about to the half (Fig. 7b) due to the evolution of gases during the decomposition process. In fact this method of synthesis produces relatively small particles that could have good catalytic properties\textsuperscript{23-25}.

**Figure 7.** SEM images of: (a) Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O; (b) Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O calcined at 700 °C for 6 hours in air.

**CONCLUSIONS**

Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5} was obtained at 700 °C by thermal decomposition of the inorganic complex Pb\textsubscript{2}[Fe(CN)\textsubscript{6}]\textsubscript{4}H\textsubscript{2}O. The complex and the decomposition products were characterized by thermal analysis (TGA and DTA), IR spectroscopy (FTIR) and powder X-ray diffraction (XPRD). The thermal decomposition occurs via two stages resulting Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5} and PbO as final products. Pb\textsubscript{2}Fe\textsubscript{2}O\textsubscript{5} crystallizes in the tetragonal system with a = b = 7.80 Å, c = 15.82 Å. PbO was indexed with the space group Pbcm and the unit cell parameters a = 5.8760 Å, b = 5.4760 Å and c = 4.7430 Å.

The size of the particles of the oxides are relatively small and it could be used with promising applications in catalysis.
