Abstract

In a biopurification system such as a biobed, the rhizosphere of the grass layer may be a significant factor for promoting pesticide dissipation in the biomixture. The rhizosphere effect of a *Lolium perenne*, *Festuca arundinacea* and *Trifolium repens* mixture on the dissipation of a pesticide combination that was composed of atrazine, chlorpyrifos and isoproturon was studied. The assay was performed using glass pots divided into two separate compartments (root surface and root-free), each filled with an organic biomixture (oat husk, top soil and peat) and contaminated with the pesticide mixture at 5 mg kg⁻¹. Non-planted and non-contaminated pots were also used as controls. The results indicated that there were high atrazine, chlorpyrifos and isoproturon dissipation in the planted pots compared with the unplanted pots. An inverse correlation was found throughout the assay between phenoloxidase activity and residual pesticide ($r=0.684$ to 0.952). Indeed, fungal biomass was positively correlated with phenoloxidase activity on day 1 ($r=0.825$) and day 30 ($r=0.855$). Besides, exudation of oxalic and malic acid in contaminated pots was higher than in the control without pesticides, associated with oxidation of the pesticide mixture in the biomixture of a biobed system. Therefore, the grass layer enhances pesticide removal in biobeds.

Keywords: Rhizosphere, pesticide dissipation, biopurification, phenoloxidase

1. Introduction

The rhizosphere can be described as the zone of soil around plant roots whereby soil properties are influenced by the presence and activity of the root (Neumann *et al.*, 2009). Because the rhizosphere continuously provides important sources of nutrients through root exudates, microbiological activity in this zone is up to four-fold greater than in soil further away from plant, resulting in a zone with higher metabolic capacities for microbiological action against both organic matter and contaminants (Haichar *et al.*, 2008). A reported mechanism used by rhizosphere microorganisms to take up contaminants by biosurfactant production, which facilitates contaminant degradation, mainly of hydrophobic compounds, and concomitantly increases their availability to plants (Read *et al.*, 2003). In this context, plant species and soil are reportedly jointly responsible for the structure and function of microbial diversity in the rhizosphere (Berg and Smalla, 2009). Plants and their associated rhizosphere microorganisms, therefore, make an important contribution to contaminant degradation in soil (Wang and Oyaizu, 2009), and their use in on-farm biopurification systems, such as biobeds, can provide huge benefits.

A biobed is a biopurification system used to minimize point source contamination by pesticides. Its main component is an organic biomixture in which the pesticides are degraded, which is composed of straw, soil and peat (2:1:1 v^v-1) (Castillo *et al.*, 2008). Generally, a layer of grass is grown on top of the biobed, which retains moisture in the biomixture and reveals pesticide spillages. However, the rhizosphere of this grass layer and its associated microorganisms could make an important contribution to improving the pesticide degradation in the biopurification system; to

date this potential has not been considered in depth in biobed studies. An important step is to identify the plant species that are capable of surviving a particular toxic contamination level in the biobed system.

Plant species with fibrous rooting systems, such as *Lolium perenne*, *Festuca arundinacea* and *Agrostis tenuis*, have demonstrated great potential for removing contaminants because they provide a large root surface area that interacts with soil microorganisms in biodegradation. *Lolium multiflorum* can increase atrazine, chlorpyrifos and pentachlorophenol removal (He *et al.*, 2008; Merini *et al.*, 2009; Urrutia *et al.*, 2013a). Singh *et al.* (2004) demonstrated that the *Pennisetum clandestinum* rhizosphere tolerated atrazine and simazine and improved their degradation compared with unplanted soil. In another work, Wang and Oyaizu (2009) evaluated the phytoremediation potential of four plant species for dibenzofuran-contaminated soil. The authors determined that *Trifolium repens* L. not only had the highest root biomass but also the highest numbers of dibenzofuran-degrading bacteria compared with three other grass species.

The aim of the present work was to evaluate the effect of the rhizosphere of a biopurification system on the dissipation of a pesticide mixture.

2. Materials and Methods

2.1. Biomixture preparation

The biomixture was prepared according to Urrutia *et al.* (2013b) using oat husk as the lignocellulosic material. It was prepared by mixing Andisol topsoil, commercial peat (43.7% organic carbon) and oat husk (OH) that was collected from crop residues (36.7%

organic carbon) in a proportion of 1:1:2 by volume. The soil (30.7% sand, 41.8% silt, 27.4% clay, 6.4% organic carbon, pH 5.2), which belonged to the Temuco series (38°42'S, 73°35'W), was collected (0-20 cm depth) and sieved (3 mm). The constituents were mixed vigorously to obtain a homogeneous biomixture, and moisture content was adjusted to 60% of the water holding capacity (WHC) by adding distilled water. The biomixture was placed in polypropylene bags for maturation and stored in the dark at $20 \pm 2^\circ\text{C}$ for 40 days before it was used in the experiments.

2.2. Experimental design

Glass pots of 18 x 17 x 9 cm (length x width x height) were used in this experiment. The pots were divided into a root compartment (RC) (6 cm in width) and a root-free compartment (RFC) (3 cm in width) and were separated by nylon mesh (25 μm). The design successfully prevented root hairs from entering adjacent zones and also kept the zones separated while allowing the transfer of microorganisms and root exudates between the compartments. In total, one hundred and forty grams of biomixture were used to fill the pots. The RC contained one hundred *Lolium perenne*, *Festuca arundinacea* and *Trifolium repens* seeds in a proportion of 50, 45 and 5%, respectively. The seeds were sown in the biomixture and covered with a layer of soil (2 g). The biomixture was maintained at 60% water holding capacity under greenhouse conditions ($22 \pm 3/18 \pm 3^\circ\text{C}$ day/night temperatures; 16/8 h light/dark photoperiod; 60-70% relative humidity) for 30 days. The pots were then contaminated with a mixture of atrazine (ATZ), isoproturon (ISP) and chlorpyrifos (CHL) in aqueous solution to reach a concentration of 5 mg kg^{-1} of each pesticide (root compartment (RC+P) and root-free

compartment (RFC+P)). Non-contaminated pots (root compartment (RC-P) and root-free compartments (RFC-P)) and unplanted pots (contaminated (C+P) and non-contaminated (C-P)) were used as controls. In total, three replicates were performed for each treatment.

The pots were arranged in a randomized design. On days 1, 15 and 30 after pesticide application, pesticide concentration, enzyme activities (β -glucosidase and phenoloxidase) and total bacteria and fungi abundance were measured in the biomixture of the different pot compartments. The grass layer root exudates (oxalic acid, malic acid, citric acid and succinic acid) were also measured.

2.3. Analytic procedure

2.3.1. Extraction and pesticide analysis

Residual pesticides were extracted from biomixtures (5 g dry weight (dw)) by shaking (1 h, 250 rpm) with 20 mL of acetone and ultrasonication (30 min). After centrifuging (10,000 rpm), 5 mL of the supernatant was collected, filtered with a polytetrafluoroethylene (PTFE) membrane (0.2- μm pore size; Millipore), evaporated with fluxed N_2 to dryness, and dissolved in 1 mL of acetonitrile:water. Pesticide concentrations were determined by high-performance liquid chromatography (HPLC).

ATZ, CHL, and ISP concentrations were determined by HPLC (Agilent Series 1100, Böblingen, Germany) that had been equipped with a diode array detector. A 150 mm x 2.1 mm i.d. Zorbax Rx-C8 analytical column and a 12.5 mm x 2.1 mm i.d. Eclipse XDB-C8 guard cartridge were used that had both been packed with diisopropyl n-octyl (5 mm). Eluent A (70%) was Milli-Q water that had been adjusted to pH 3, and eluent B was acetonitrile. The gradient condition used

for separating the pesticides was 3 min 30% B, 4–5 min 35% B, 6–8 min 40% B, 9–13 min 60% B, 14–22 min 70% B, and 23–32 min 30% B. The flow rate was constant at 0.2 mL min⁻¹. Column temperature was maintained at 30±1°C. The detector was set at three wavelengths for data acquisition: 220, 245 and 288 nm. Instrument calibrations and quantifications were performed against pure reference standards (0.5–5 mg L⁻¹) for each compound. Recovery of ATZ, CHL and ISP was > 90%.

2.3.2. Enzyme activity analyses

Phenoloxidase activity was assessed using the MBTH/DMAB method (adapted from Castillo *et al* (1994). Briefly, samples (10 g dw) of the biomixture were shaken (150 rpm, 2 h) with 25 mL of a 100 mM succinate-lactate buffer (pH 4.5). The samples were centrifuged (4,000 rpm, 20 min). The supernatant of each sample was collected, filtered through a 0.45-µm membrane and measured immediately. The reaction mixture contained 300 µL of 6.6 mM DMAB, 100 µL of 1.4 mM MBTH, 30 µL of 20 mM MnSO₄ and 1560 µL of the filtered sample. The reaction was observed in a Spectronic Genesis 2PC spectrophotometer at 590 nm ($\epsilon = 0.053 \mu\text{M}^{-1} \text{cm}^{-1}$). No correction was made for the possible presence of lignin peroxidase (LiP) and Laccase (Lac) activity. Thus, the measurement may represent the sum of manganese peroxidase (MnP), LiP and Lac activity but is expressed as phenoloxidase activity (Castillo and Torstensson, 2007).

β -glucosidase activity was analysed by determining the amount of p-nitrophenol (PNP) produced from 4-nitrophenyl- β -D glucanopyranoside (PNG) as described by Tabatabai (1982). Enzyme activity was determined in triplicate using 0.2 g of the biomixture sample.

2.3.3. DNA extraction from the biomixture

Total DNA was extracted from 250 mg dw of each of the three samples taken from the biomixture of the pots. Each sample was mixed with a solution of 100 mM Tris (pH 8.0), 100 mM EDTA (pH 8.0), 100 mM NaCl, and 2% (w v⁻¹) sodium dodecyl sulphate. Glass beads of different diameters were added in a bead-beater tube, and the biomixture solution was shaken for 30 s at 1,600 rpm in a mini bead-beater cell disruptor (Mikro-Dismembrator; S.B. Braun Biotech International) before centrifuging at 12,235 rpm for 1 min. For protein precipitation, the supernatants were incubated on ice for 10 min with a 1/10 volume of 3 M sodium acetate and centrifuged (12,235 rpm, 5 min, 4°C). In the last step, nucleic acids were precipitated from the supernatants by adding 1 volume of ice-cold isopropanol. For DNA purification, polyvinylpolypyrrolidone (PVPP, Sigma-Aldrich, USA) columns were used and were prepared by adding 92–95 mg (i.e., 1.2 cm) of PVPP powder to Micro-Spin Chromatography columns (Bio-Rad, USA). The tubes were centrifuged (2 min, 3,270 rpm) with 400 µL H₂O. This procedure was repeated a second time. DNA extracts were then purified using PVPP columns (3,270 rpm, 4 min, 10 °C) (Petric *et al.*, 2011).

2.3.4. Real-Time PCR Quantification (Q-PCR) of bacteria and fungi

Total bacteria and fungi abundance in the biomixture was quantified using small ribosomal subunit 16S and 18Sr RNA genes. For this purpose, the primer sets 341F 5'-CCTACGGGAGGCAGCAG-3', 518R 5'-ATTACCGCGGCTGCTGG-3' (Muyser *et al*, 1993) and FR1 5'-A(I)CCATTCAATCGGTAXT-3', FF390 5'-CGATAACGAACGAGACCT-3' were (Vainio and Hantula, 2000) selected for bacteria and

fungi, respectively. An assembly of 16S rRNA and 18Sr RNA genes in pGEMT easy vector (Promega) plasmids using *Pseudomonas putida* KT2440 and *Fusarium oxysporum* JX910900, standard curves, and bacterial and fungal Q-PCR conditions were performed according to Castillo *et al* (2013). Reactions were conducted in an iCycler MyiQ™ System (Bio-rad, USA) using the SybrGreen® detection system. The reaction was performed in a final volume of 15 µL containing 7.5 µL iQ™ SYBR® Green Supermix, 0.5 µM of each primer, 0.5 mg mL⁻¹ bovine serum albumin (BSA) and 2 ng of template DNA. The function values describe the relationship between the Ct (threshold cycle), and the sequence number of each bacteria and fungi are -3.28 and -3.10, respectively, with a PCR efficiency of 101% and 109%. Controls without templates gave null or negligible values.

2.3.5. Extraction and root exudate analysis

Organic acids were collected from the grass layer at 1, 15 and 30 days. The roots were washed with distilled water and then placed in 50 mL of distilled water for 30 min; 5 mL was filtered through a PTFE membrane (0.2-µm pore size, Millipore), and the organic acid concentration was determined by high-performance liquid chromatography (HPLC). Root exudates were standardized by root dry weight, which was measured immediately after treatment.

Oxalic acid, malic acid, citric acid and succinic acid concentrations were determined by HPLC using a Merck Hitachi L-7100 pump, a Rheodyne 7725 injector with a 20 µL loop and a Merck Hitachi L-7455 diode array detector. Separation was performed using a C18 column (Purospher Star RP-C18e, 5 µm 4.6 x 150 mm) with a guard column (LichroCART RP-C18e, 5 µm 4 x 4 mm). Eluent A was methanol, and eluent B was phosphate buffer. The gradient condition used for organic acid separation was 0–15 min of 7% A. The flow rate was set

at 0–15 min at 1.0 mL min⁻¹. The column temperature was maintained at 30 ± 1 °C. The detector was set at 210 nm for data acquisition. Instrument calibrations and quantifications were performed against pure reference standards (0.1–10 mg L⁻¹) for each compound. Recovery of each organic acid was > 90%.

2.3.6. Statistical data analysis

The experiment was conducted with three independent replicates. The pesticide measurement, enzyme activities and size of the total bacterial and fungal community during the dissipation period were subjected to one-way ANOVA, and the averages were compared using the Tukey multiple range test at $p \leq 0.05$ to identify significant effects of different treatments on the same sampling day. Pearson correlations were used to assess the relationships between pesticides and phenoloxidase activity as well as the relationships between phenoloxidase activity and fungal biomass on days 1 and 30. To estimate a possible change in root exudate organic acids caused by the pesticide addition in the planted pots, the data were compared (contaminated pots (RC+P) and non-contaminated pot (RC-P)) using Student's t-test.

3. Results and Discussion

3.1. Dissipation of ATZ, CHL and ISP

The effect of the rhizosphere on ATZ, CHL and ISP dissipation in the biomixtures of the biobed system is demonstrated in Figure 1 a, b and c. Generally, the grass layer increased the removal of the three pesticides. The data indicates a higher dissipation of the three pesticides in all sampling days in the RC+P compartment. On sampling day 1, the dissipation of ATZ, CHL and ISP in the RC+P compartment were 15.46, 13.83 and 25.55%, respectively. Similar results

were observed in the RFC+P compartment (12.85, 9.57 and 24.60%, respectively, for ATZ, CHL and ISP dissipation). In contrast, the dissipation rates of ATZ, CHL and ISP in the unplanted pot (C+P) were 0, 5.4 and 3.9%, respectively. Pesticide dissipation

on day 15 was significantly higher ($p<0.05$) in the RC+P compartment compared with the unplanted C+P treatment. At the end of the trial (30 days incubation), removal from the RC+P compartment was higher than from the unplanted biomixture (C+P) by 20.3%, 24.4% and 22.35% for ATZ, CHL and ISP, respectively.

Figure 1. Pesticide removal (%) after 1, 15 and 30 d for ATZ (a), CHL (b) and ISP (c) at 5 mg kg⁻¹ in the biomixtures planted (root compartment (RC+P) and root-free compartment (RFC+P)) and unplanted pots (C+P). Each value is the mean of three replicates with error bars showing the standard deviation of the mean. Different letters refer to significant differences in mean values among the different treatments of each pesticide

These results agree with several reports demonstrating that the rhizosphere of tolerant plant species was effective in promoting the dissipation of different contaminants. The presence of mangrove roots improved phenanthrene and pyrene dissipation by 47.7% and 37.6%, respectively, compared with unplanted treatment values of 26.2% and 22.8%, respectively, after 60 days (Lu *et al.*, 2001). In another work, *Lolium multiflorum* displayed a 20% higher atrazine removal capacity than bulk soil after 21 days of incubation (Merini *et al.*, 2009). *L. multiflorum* likewise displayed high pentachlorophenol (PCP) removal (>96%) in a planted rhizotron system compared with unplanted treatments in which PCP dissipation was approximately 36% (Urrutia *et al.*, 2013a).

Furthermore, dissipation of the three pesticides in the root-free compartment close to the rhizosphere (RFC+P) showed no-significant differences compared with the rhizosphere compartment (RC+P) at almost all assay times (Figure 1); this may demonstrate the influence of the root exudates in microbial composition and activity given that they are capable of degrading ATZ, CHL and ISP. Similar results were reported by He *et al.* (2005), who found higher pentachlorophenol degradation in the root compartment and the six separated compartments at various distances from the root surface of a planted rhizobox system compared with unplanted treatments. The authors attributed this finding to the beneficial effect on the degradation of root exudates and their interaction with microbial activity.

3.2. Enzyme activity analysis

β -glucosidase activity displayed different responses in planted and unplanted treatments (Figure 2a). Specifically, lower values were observed in the C+P treatment for all days. Since, β -glucosidases

are enzymes involved in the mineralization of organic materials as they catalyse the hydrolysis of terminations of the β -D-glucose chain releasing β -glucose that become available for microorganisms. This enzymatic activity can be considered a soil quality indicator, as it indicates changes in organic matter in the soil. Moreover, herbicide presence can decrease β -glucosidase activity, due to that microbial viability is affected (Moreno *et al.*, 2011). However, plants significantly ($p < 0.05$) increased β -glucosidase activity, which was higher in the RC+P and RFC+P compartments than in the non-contaminated treatments on days 15 and 30. In this context, Hernández-Allica *et al.* (2006) reported that higher β -glucosidase activity was observed in metal-polluted soil planted with *Thlaspi caerulescens* than in unplanted treatments. These results may be related to the organic compounds released by the plant roots, which enhance microbial biomass and activity.

The presence of plants in the different treatments likewise stimulated phenoloxidase activity, as demonstrated in Figure 2b. Phenoloxidase activity has been reported as the most important biological activity for contaminant degradation in soil (Briceño *et al.*, 2007; Diez, 2010) and in the biomixture of the biobed system (Castillo *et al.*, 2008). Our results demonstrated that both compartments of the contaminated pots (RC+P and RFC+P) displayed a significant increase ($P < 0.05$) in phenoloxidase activity compared with unplanted treatments (C+P and C-P) on days 1, 15 and 30. These results are in agreement with those of Lee *et al.* (2008), who observed that the presence of plant roots in soil contaminated with phenanthrene and pyrene (PAHs) increased the amount of peroxidase activity and PAH dissipation compared with unplanted pots.

Therefore, plant-microbe interactions in the fungi-containing root zone, including the formation of

symbiotic mycorrhiza, may produce exoenzymes, such as peroxidases in the rhizosphere; these enzymes may play an important role in the detoxification of soil contaminants, as showed in our results. However, this effect varies with plant species as well as environmental factors such as the nutrient status of the matrix (Chaudhry *et al.*, 2005).

A significant correlation was observed between phenoloxidase activity and residual pesticide concentration for all sampling days (Table 1). The residual concentrations of ATZ, CHL and ISP

presented a negative correlation with phenoloxidase activity, with the correlation coefficient ranging from 0.684 to 0.952. These values suggest that these enzymes may be involved in the dissipation of these pesticides. Castillo and Torstensson (2007) reported that the degradation of metamitron, chloridazon, isoproturon, and linuron was correlated with phenoloxidase activity in the biobed system biomixtures.

Figure 2. β -glucosidase activity (a), phenoloxidase activity (b) in the biomixture contaminated with 5 mg kg⁻¹ concentrations of pesticides, in planted pots (root compartment (RC+P) and root- free compartment (RFC+P)) and unplanted pots (C+P). In addition, non-contaminated pots (root compartment (RC-P) and root- free compartment (RFC-P)) and unplanted pots (C-P) were used as controls during the incubation time. Each value is the mean of three replicates with error bars showing the standard deviation of the mean. Different letters refer to significant differences in the mean values among different treatments of each pesticide on the same day.

Figure 3. Estimation of the fungal (a) and bacterial (b) population size in the biomixtures contaminated with 5 mg kg⁻¹ concentration of pesticides, in planted pots (root compartment (RC+P) and root-free compartment (RFC+P)) and unplanted pots (C+P). In addition, non-contaminated pots (root compartment (RC-P) and root-free compartment (RFC-P)) and unplanted pots (C-P) were used as controls, during the incubation time. Each value is the mean of three replicates with error bars showing the standard deviation of the mean. Different letters refer to significant differences in mean values among different treatments of each pesticide on the same day.

3.3. Real-Time PCR Quantification (Q-PCR) of bacteria and fungi

The fungal and bacterial populations were estimated by real-time PCR (Figure 3a and b). Fungal and bacterial gene copy numbers were increased in planted biomixtures compared with unplanted biomixtures on day 30. The total fungal community was significantly larger ($p < 0.05$) in the biomixtures that were contaminated unplanted contaminated biomixtures (C+P) on days 1

and 30, displaying the same pesticide removal pattern observed previously in the contaminated treatments. In control treatments without pesticides, higher values were detected in planted treatments in both compartments compared with unplanted pots. The RFC-P compartment displayed a larger biomass (7.34×10^6 copy number ng⁻¹ DNA) on day 30, consistent with the high phenoloxidase activity detected on the same day. These results indicate that fungal biomass and activity were greatly increased in the biobed system biomixtures

with a grass layer. Fungal population size was positively correlated with phenoloxidase activity on day 1 ($r=0.825$) and day 30 ($r=0.855$). The rhizosphere effect was therefore positive, favouring ATZ, CHL and ISP dissipation in the biomixtures. Conversely, bacterial community size in the planted pots on day 1 displayed no significant differences ($p<0.05$), and only the C-P treatment size was higher. However, in planted pots (RC+P, RFC+P and RFC-P), the bacterial copy number was higher than in the other treatments on day 30. The increase in population size could have also contributed to higher pesticide

dissipation compared with unplanted pots.

Our results are comparable with those of He *et al.* (2005), who reported that in a rhizobox system the planted treatments (root compartment) significantly increased microbial biomass, especially in the near-rhizosphere, which enhanced pentachlorophenol degradation in soil. These differences observed between soil with and without plants as well as among sampling zones in varying proximity to roots were expected on the basis of microbial growth and community structure modified by root exudates.

Table 1. Significant correlation between phenoloxidase activity and residual concentration of atrazine (ATZ), chlorpyrifos (CHL) and isoproturon (ISP) in the biobed biomixtures of different treatments.

	Time (day)	ATZ	CHL	ISP
Phenoloxidase activity	1	-0.910**	-0.691*	-0.882**
	15	-0.878**	-0.684*	-0.935**
	30	-0.818**	-0.952**	-0.840**

*correlation is significant at the 0.05 level (bilateral)

**correlation is significant at the 0.01 level (bilateral)

3.4. Root exudate organic acids

The range of organic acids exuded by roots varies by plants, but oxalic, benzoic, maleic, succinic, lactic, malic and citric acids were frequently observed in most plant species (Strobel, 2001). Figure 4 shown the oxalic acid, malic acid, citric acid and succinic acid exuded by roots of *L. perenne*, *F. arundinacea* and *T. repens*, which were planted in a proportion of 50, 45 and 5 %, respectively. Overall, the four organic acids were detected in all of the sampling days, and oxalic acid and malic acid concentrations were

higher in contaminated pots than in control samples. Conversely, the citric acid concentration was the lowest ($<0.5 \text{ mg L}^{-1}$) and succinic acid the highest (5 mg L^{-1}); however, their behaviour patterns were similar with higher production in treatments without pesticides than in contaminated pots. Oxalic acid was significantly ($p<0.05$) higher in contaminated pots at day 30 compared with the control without pesticides, and its production increased during the incubation period in both treatments. Significantly ($p<0.05$) higher malic acid production was detected all over the time in pesticide treatments than in the

Figure 4. Root exudation of oxalic acid (a), malic acid (b), citric acid (c) and succinic acid (d), under pesticide mixture contamination (ATZ, CHL and ISP at 5 mg kg^{-1}) and control treatments without pesticides, during the incubation time. Each value is the mean of three replicates with error bars showing the standard deviation of the mean. * refer to significant differences in mean values between contaminated and non-contaminated treatment on the same day (Student's t-test, $p < 0.05$).

control, and its production was more than double compared with the pots without pesticides.

Organic acid exudations depend on several environmental factors and are involved in many soil and plant processes, such as mobilization and nutrient uptake by plants and microorganisms, detoxification of metals by plants, microbial proliferation in the rhizosphere and dissolution of soil minerals (Ryan *et al.*, 2001). It is difficult to determine the role of these specific organic acids in ATZ, CHL and ISP dissipation; however, our

results demonstrated that oxalic acid and malic acid concentrations were higher in response to pesticide contamination. Root exudates, particularly oxalic and malic acids, are capable of chelation, which is related to phenoloxidase stimulation including MnP because organic chelators, such as oxalate and malate, produced by ligninolytic fungi (e.g., white rot fungi) can stabilize Mn^{3+} and thereby stimulate lignin-degrading enzyme activities (Hakala *et al.*, 2005; Marco-Urrea and Reddy, 2012).

These organic acids could therefore be involved in the enhanced oxidation of the pesticides in planted pots. The above is related to the increased fungal population that was observed in the rhizosphere of the compartment with the pesticide addition (Figure 3a). Walton *et al.* (1994) demonstrated that plants can respond to chemical stress by increasing radical exudation, which affects rhizosphere microorganism composition or activity and enables them to degrade toxicants.

Our results demonstrated that pesticide contamination caused slightly negative effects in citric acid exudation at all days of the assay and succinic acid exudation at day 30. Moreover, significant decreases ($p < 0.05$) were observed in succinic acid exudation at day 1 and 15 compared with the control. These findings suggested that root exudation of organic acids changed with pesticide contamination. Similarly, Wang *et al.* (2014) reported that succinic acid and lactic acid exudation in the rhizosphere of mangrove plants enhanced mixed polycyclic aromatic hydrocarbon (PAH) removal in contaminated sediment compared with unplanted control. *B. gymnorhiza* had significant positive correlations between lactic acid and PAH contamination levels, while citric acid revealed significant negative correlations with PAH levels in two other species (*K. obovata* and *A. marina*). They suggested that organic acid exudation changed PAHs contamination and different plant species.

4. Conclusion

The rhizosphere effect significantly enhanced atrazine, chlorpyrifos and isoproturon dissipation in an organic biomixture. The largest and most rapid loss of pesticides in the planted pots was in the root compartment followed by the root-free compartment due to microorganism and root exudate transfer between compartments. The enhanced pesticide dissipation was accompanied by an increase in oxalic acid and

malic acid exudation concentrations, which induced lignin-degrading enzyme activities (phenoloxidase activity). Moreover, a high relative abundance of fungal and bacterial population was detected. Our results demonstrated that the grass layer is a significant positive factor for promoting pesticide removal in the biobed system.
