Abstract

For a given nonnegative $n \times n$ matrix A consider the following quantity

$$s(A^m) := \frac{\min_{i,j}(A^m)_{ij}}{\max_{i,j}(A^m)_{ij}}, \quad m = 1, 2, \dots$$

as long as the denominator is positive. It is simply the ratio between the smallest and the largest entries of A^m . We call $s(A^m)$ the inverse spread of A^m which is interpreted as a measure of the maximum variation among the entries of A^m in the multiplicative and reciprocal sense. Smaller $s(A^m)$ means a larger variation for A^m . Clearly $0 \leq s(A^m) \leq 1$ for all $m = 1, 2, \dots$. We study the asymptotic behavior of $s(A^m)$, that is, the behavior of $s(A^m)$ as $m \rightarrow \infty$. The study arises from evolutionary biology.

1. Introduction

Probabilistic models of protein evolution have been developed and refined over time to account for the biological processes involved in amino acid substitution, i.e., mutational biases in the DNA, translation of the DNA into protein according to the genetic code, and selective constraints on the protein [10, 11]. These models have been used primarily to calculate distances between sequences for use in phylogenetic reconstruction.

Here we use graph theory to focus on the initial stages of the substitution process, and ask if there are biases toward particular amino acid identities in the initial steps of protein evolution, for example at the advent of a new protein(s) following a gene duplication, recombination, or hybridization event. Rather than seeking the shortest distance among a set of given sequences through parameterized substitution models, we modeled the problem with graphs where the vertices are either DNA codons in G_1 or amino acids in G_2 through G_4 , with the associated adjacency matrices M_1 , M_2 , M_3 and M_4 respectively. G_1 and G_2 model evolutionary transitions in terms of the mutational distance between two codon states, or two amino acid states respectively. The remaining two graphs consider amino acid transitions in terms of their likelihood as determined through comparisons of real proteins [6].

The vertices of G_1 are the possible 3 letter combinations of nucleotides (A, T, C, G) that comprise the genetic code. In the Genetic Code, each three letter combination, or codon, codes for an amino acid, the building block of proteins, with a typical protein consisting in 200-800 amino acids. The edges of G_1 correspond to the hamming distance between any two codons (i.e. $\{u, v\}$ is an edge in G_1 if the codons corresponding to u and v differ in exactly one nucleotide). The entries in the adjacency matrix are either a 1 or a 0. A one indicates that the codons are only a single letter change apart; only a single mutational event separates the states and no intermediate must be traversed to arrive at the new identity. A zero indicates that more than a single nucleotide difference separates the codons, and a potentially maladaptive intermediate codon must be traversed to evolve from one codon to the other. In this way, G_1 models transitions at the level of DNA evolution, how does the fact that, from a given codon state, only nine of the 63 non-identical codons can be reached in a single mutational step affect evolutionary outcomes?

G_2 models evolutionary transitions at the level of amino acid evolution by incorporating the degeneracy in the genetic code into the graph - the

64 codons code for only twenty different amino acids. Each amino acid is coded by from one to six different codons, with the difference affecting the number of single-step pathways, and therefore the likelihood of evolution, between two amino acid states. The vertices of G_2 are the 20 amino acids, with the edges containing the number of single step pathways between two amino acids when degeneracy in the code is considered. For example, there are two ways to code the amino acid Histidine (His), CAT and CAC, and two ways to code Glutamine (Gln), CAA and CAG, thus there are four single step paths between His and Gln, and hence there are four edges between the vertices His and Gln. The following is the adjacency matrix M_2 associated with G_2 :

$$M_2 = \begin{pmatrix} & \text{A} & \text{R} & \text{N} & \text{D} & \text{C} & \text{Q} & \text{E} & \text{G} & \text{H} & \text{I} & \text{L} & \text{K} & \text{M} & \text{F} & \text{P} & \text{S} & \text{T} & \text{W} & \text{Y} & \text{V} \\ \text{ALA(A)} & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 4 & 0 & 0 & 0 & 0 & 0 & 0 & 4 & 4 & 4 & 0 & 0 & 4 \\ \text{ARG(R)} & 0 & 0 & 0 & 0 & 2 & 2 & 0 & 6 & 2 & 1 & 4 & 2 & 1 & 0 & 4 & 6 & 2 & 2 & 0 & 0 \\ \text{ASN(N)} & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 2 & 2 & 0 & 4 & 0 & 0 & 0 & 2 & 2 & 0 & 2 & 0 \\ \text{ASP(D)} & 2 & 0 & 2 & 0 & 0 & 0 & 4 & 2 & 2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2 & 2 \\ \text{CYS(C)} & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 4 & 0 & 2 & 2 & 0 \\ \text{GLN(Q)} & 0 & 2 & 0 & 0 & 0 & 0 & 2 & 0 & 4 & 0 & 2 & 2 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 \\ \text{GLU(E)} & 2 & 0 & 0 & 4 & 0 & 2 & 0 & 2 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2 \\ \text{GLY(G)} & 4 & 6 & 0 & 2 & 2 & 0 & 2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 2 & 0 & 1 & 0 & 4 \\ \text{HIS(H)} & 0 & 2 & 2 & 2 & 0 & 4 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 2 & 0 \\ \text{ILE(I)} & 0 & 1 & 2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 4 & 1 & 3 & 2 & 0 & 2 & 3 & 0 & 0 & 3 \\ \text{LEU(L)} & 0 & 4 & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 4 & 0 & 0 & 2 & 6 & 4 & 2 & 0 & 1 & 0 & 6 \\ \text{LYS(K)} & 0 & 2 & 4 & 0 & 0 & 2 & 2 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 2 & 0 & 0 & 0 \\ \text{MET(M)} & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 3 & 2 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 \\ \text{PHE(F)} & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 2 & 6 & 0 & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 2 \\ \text{PRO(P)} & 4 & 4 & 0 & 0 & 0 & 2 & 0 & 0 & 2 & 0 & 4 & 0 & 0 & 0 & 0 & 4 & 4 & 0 & 0 & 0 \\ \text{SER(S)} & 4 & 6 & 2 & 0 & 4 & 0 & 0 & 2 & 0 & 2 & 2 & 0 & 0 & 2 & 4 & 0 & 6 & 1 & 2 & 0 \\ \text{THR(T)} & 4 & 2 & 2 & 0 & 0 & 0 & 0 & 0 & 0 & 3 & 0 & 2 & 1 & 0 & 4 & 6 & 0 & 0 & 0 & 0 \\ \text{TRP(W)} & 0 & 2 & 0 & 0 & 2 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ \text{TYR(Y)} & 0 & 0 & 2 & 2 & 2 & 0 & 0 & 0 & 2 & 0 & 0 & 0 & 0 & 2 & 0 & 2 & 0 & 0 & 0 & 0 \\ \text{VAL(V)} & 4 & 0 & 0 & 2 & 0 & 0 & 2 & 4 & 0 & 3 & 6 & 0 & 1 & 2 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

The vertices of G_3 and G_4 also correspond to the twenty amino acids, however the edges are different. These consist of the likelihood of a transition between amino acid states as determined through comparisons of real proteins (multiplied by 10^5) [6]. Amino acids with similar biochemistry are more likely to substitute for one another than amino acids with very different biochemistry, as the latter type of transition is more likely to disrupt

protein function. G_3 considers transitions under a model of purifying selection, in which most mutations, ie. evolutionary transitions, are deleterious, such that the most likely evolutionary transition is a transition to the same amino acid state. However, in rare instances, positive selection, transitions to different amino acid states are favored. This condition is modeled by the graph G_4 , in which transitions to the same amino acid are not allowed (i.e. deleting all the loops in G_3 to create G_4 or placing zeros on the main diagonal of M_3 to obtain M_4). The matrices M_1 , M_2 , M_3 , and M_4 are on the following URL:

[http : //academic.udayton.edu/AtifAbueida/Positive_Matrix.htm](http://academic.udayton.edu/AtifAbueida/Positive_Matrix.htm)

By raising the matrix to integer powers, m , the codon or amino acid evolves, such that the (i, j) entry in the matrix, a_{ij} , represents the number of m -step pathways between the codon states in the i^{th} row and j^{th} column in question. By evolving the matrix, the following questions are answered:

1. Are evolutionary pathways unevenly distributed, such that there are more pathways to some codon identities than others, and
2. If so, how long does the uneven distribution of pathways persist?

Figure 1. Min/Max vs. nucleotide matrix powers

Results from G_1 show that the number of pathways to different codon states are unevenly distributed early in the evolution of the matrix ; the ratio of the smallest entry to the largest entry in the matrix (Min/Max, or Inverse spread) is less than 1.0. After ten generations of evolution this signal disappears; over time, the accumulation of alternative pathways between codon states results in every codon state being equally likely (redMin/Max

= 1.0. After ten generations of evolution this signal disappears; over time, the accumulation of alternative pathways between codon states results in every codon state being equally likely (Fig. 1).

G_2 reveals that degeneracy in the genetic code impacts the evolutionary process. G_2 reaches an equilibrium min/max value in fewer generations than the nucleotide matrix (Fig. 2). The equilibrium value of 0.0469 is smaller than the (non-zero) min/max in the initial (A-zero) matrix (0.167).

Figure 2. Min/Max vs. amino acid coding matrix powers

G_3 and G_4 show different behavior than G_2 , expected given the fundamental role of functional considerations in evolution. After 2000 generations, the purifying selection matrix G_3 arrives at a min/max approaching 0.1145. This value is larger than the initial, non-zero min/max of 0.00001 in the (A-zero) matrix.

Figure 3. Min/Max vs. Purifying selection matrix powers

After 10 generations, the functional adjacency matrix, M_4 , arrives at a min/max equilibrium of 0.00496 (see figure), larger than the (non-zero) min/max value in the (A-zero) matrix. This value is larger than the (non-zero) min/max in the initial (A-zero) matrix (.00016).

Figure 4. Min/Max vs. Positive selection matrix powers

The above figures all point to a possible conclusion that the inverse spread of A^m settles at some constant, where A is a nonnegative $n \times n$ matrix, for example, $A = M_1, M_2, M_3$ and M_4 are nonnegative matrices. It turns out it is true under certain circumstances. We discuss the inverse spread phenomenon in more mathematical form and we show when it converges. The matrices M_1, M_2, M_3 and M_4 are indeed primitive matrices which will be discussed in a later section.

2. Preliminaries on nonnegative matrices

Let $\mathbf{N}_n$ denote the collection all nonnegative $n \times n$ matrices. See [1, 5] for preliminaries for nonnegative matrices. To have a well defined $s(A^m)$, $A^m \in \mathbf{N}_n$ must have at least one nonzero entry. But this can be violated by the so called *nilpotent* matrices. A nilpotent $n \times n$ matrix A is a matrix such that $A^k = 0$ for some positive integer k . Indeed the smallest such k is no greater than n . For example

$$N = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$$

is a nilpotent matrix since $N^2 = 0$. Clearly $s(N^2)$ is undefined. So we need to restrict our study to nonnegative non-nilpotent matrices. It is known that a (complex or real) square matrix A is nilpotent if and only if all eigenvalues of A are zeros. But this fact may not offer much help in practice to determine whether $A \in \mathbf{N}_n$ is nilpotent or not because of the presence of numerical error, especially when dealing with large matrices, for example, M_1 is 64×64 . Hearon [4] obtained the following characterization of nonnegative nilpotent matrices. The third condition makes a good check on whether $A \in \mathbf{N}_n$ is nilpotent. An algorithm to find cycles in directed graph has been developed in [9] which is useful to check the last condition.

Theorem 3. (Hearon) *Let $A \in \mathbf{N}_n$. Then the following are equivalent.*

1. A is nilpotent.
2. A is permutationally similar to a triangular matrix with zero diagonal entries.
3. A and each of its principal submatrices contain a zero row and a zero column.
4. the graph $G(A)$ of A contains no cycles.

The graph $G(A)$ of $A \in \mathbf{N}_n$ is constructed in the following fashion (also works for any $n \times n$ matrix): we begin with n points or vertices $v_1, \dots, v_n$. If $a_{ij} \neq 0$ we draw a directed line (arrow) from j to i . In particular if $i = j$, we draw a loop on v_j . A cycle of length k is obtained from a path of length k by adding the arrow connecting their terminal vertex to the initial vertex. For example, $v_2 \rightarrow v_5 \rightarrow v_4 \rightarrow v_2$ is a cycle of length 3. We regard a loop $v_i \rightarrow v_i$ as a cycle of length 1.

For our application, we can check $A^n = 0$ to see whether $A \in \mathbf{N}_n$ is nilpotent or not, provided that the size of A is not too large.

Another practical criterion for nilpotence of $A \in \mathbf{N}_n$ is $\text{tr } A^k = 0$ for all $k = 1, \dots, n$ [5, p.44], where $\text{tr } A^k$ denotes the trace of A^k , i.e., the sum of the diagonal entries of A^k , especially the entries of our matrices are nonnegative integers.

To carry our study further we need more concepts for nonnegative matrices.

A matrix $A \in \mathbf{N}_n$ is said to be *reducible* if there exists a permutation matrix P such that

$$PAP^T = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$$

where B and D are square matrices but not necessarily of the same size. Otherwise P is said to be *irreducible*. The following result contains some characterizations of irreducible nonnegative matrices [5, p.362].

Theorem 5. *Let $A \in \mathbf{N}_n$. Then the following are equivalent.*

1. A is irreducible.
2. $(I + A)^{n-1} > 0$.
3. the graph $G(A)$ is strongly connected.

The graph $G(A)$ is *strongly connected* if between every pair of distinct vertices v_i, v_j , there is a directed path that begins at v_i and ends at v_j . Condition 2 in Theorem 5 is useful to have computer implementation if the entries of A are nonnegative integers like M_1, M_2, M_3 .

Notice that if A is reducible and non-nilpotent, then

$$PAP^T = \begin{pmatrix} B & C \\ 0 & D \end{pmatrix}$$

where B and D are square matrices and thus

$$PA^mP^T = \begin{pmatrix} B^m & * \\ 0 & D^m \end{pmatrix}$$

Since P is a permutation matrix, the entries of A are those of PA^mP^T . So it is clear now

$$s(A^m) = 0, \quad m = 1, 2, \dots$$

We thus turn our attention to the irreducible nonnegative matrices.

3. The limit of inverse spread for irreducible nonnegative matrices

An irreducible nonnegative matrix A is non-nilpotent by Theorem 3. By Perron-Frobenius theory [1, 3, 5], a nonnegative irreducible matrix A has the spectral radius, $r(A)$, as a simple eigenvalue. The spectral radius of A is the maximal large eigenvalue modulus. However it is possible for A to have some eigenvalue λ other than $r(A)$ such that the modulus of λ is also $r(A)$. Suppose A has k eigenvalues of maximal modulus $r(A)$, including $r(A)$. When $k = 1$, A is called *primitive*; when $k > 1$, A is called *imprimitive of index k* . For each imprimitive matrix A with index k , there exists a permutation matrix P such that

$$PAP^T = \begin{pmatrix} 0 & B_1 & & & \\ & 0 & B_2 & & \\ & & & \ddots & \\ & & & & 0 & B_{k-1} \\ B_k & & & & & 0 \end{pmatrix}$$

where the diagonal zero blocks are square. Moreover the diagonal blocks in $PA^kP^T = \text{diag}(A_1, \dots, A_k)$ are all primitive and have one and the same maximal eigenvalue. Indeed one can see

$$PA^2P^T = \begin{pmatrix} 0 & 0 & B_1B_2 & & \\ & 0 & 0 & B_2B_3 & \\ & & & \ddots & \\ & & & & 0 & B_{k-2}B_{k-1} \\ B_{k-1}B_k & & & & 0 & 0 \\ & B_kB_1 & & & 0 & 0 \end{pmatrix}$$

and so on. So PA^mP^T would always have some zero entry for any positive integer m . Thus $s(A^m) = 0$ for all $m = 1, 2, \dots$ if A is imprimitive of index $k > 1$.

So we only need to consider primitive A . It is known that [5, p.516] $A \in \mathbf{N}_n$ is primitive if and only if $A^p > 0$ for some positive integer p and one may pick $p = n^2 - 2n + 2$ [5, p.520].

From [3, p.81]

$$\lim_{m \rightarrow \infty} \frac{A^m}{r^m} = \frac{C(r)}{\psi'(r)},$$

where $\psi(\lambda)$ is the minimal polynomial of A , $\psi'(\lambda)$ its derivative, $C(\lambda) := (\lambda I_n - A)^{-1}\psi(\lambda)$ is the reduced adjoint matrix [2, p.90], and $r := r(A)$. So

$$\begin{aligned} s(A^m) &= \lim_{m \rightarrow \infty} \frac{\min_{i,j}(A^m)_{ij}}{\max_{i,j}(A^m)_{ij}} \\ &= \lim_{m \rightarrow \infty} \frac{\min_{i,j}(A^m/r^m)_{ij}}{\max_{i,j}(A^m/r^m)_{ij}} \\ &= \frac{\min_{i,j} \lim_{m \rightarrow \infty} (A^m/r^m)_{ij}}{\max_{i,j} \lim_{m \rightarrow \infty} (A^m/r^m)_{ij}} \\ &= \frac{\min_{i,j}(C(r)/\psi'(r))_{ij}}{\max_{i,j}(C(r)/\psi'(r))_{ij}} \\ &= \frac{\min_{i,j}(C(r))_{ij}}{\max_{i,j}(C(r))_{ij}} \end{aligned}$$

To summarize:

Theorem 4. *Let $A \in \mathbf{N}_n$ be a non-nilpotent nonnegative matrix.*

1. *If A is primitive, then $\ell(A) := \lim_{m \rightarrow \infty} s(A^m)$ exists and $0 < \ell(A) \leq 1$.*

Indeed

$$\ell(A) = \frac{\min_{i,j}(C(r))_{ij}}{\max_{i,j}(C(r))_{ij}},$$

where $C(\lambda)$ is the reduced adjoint matrix $C(\lambda) = (\lambda I_n - A)^{-1}\psi(\lambda)$ and $\psi(\lambda)$ is the minimal characteristic polynomial of A .

2. *Otherwise $\ell(A) := \lim_{m \rightarrow \infty} s(A^m) = 0$.*

There is another way to compute $\ell(A)$ for a primitive $A \in \mathbf{N}_n$. Since [5, p.516]

$$(3.1) \quad \lim_{m \rightarrow \infty} A^m/r^m = L,$$

where $L = xy^T$, $Ax = r(A)x$ and $A^T y = r(A)y$, $x > 0$, $y > 0$ and $x^T y = 1$. So

$$\begin{aligned} (3.2) \quad \ell(A) &= \frac{\min_{1 \leq i,j \leq n} (xy^T)_{ij}}{\max_{1 \leq i,j \leq n} (xy^T)_{ij}} = \frac{\min_{1 \leq i,j \leq n} x_i y_j}{\max_{1 \leq i,j \leq n} x_i y_j} \\ &= \min_{1 \leq i,j \leq n} \frac{x_i}{x_j} \min_{1 \leq i,j \leq n} \frac{y_i}{y_j}. \end{aligned}$$

Thus finding $\ell(A)$ is reduced to the minimum ratios of the components in the Perron vectors of A and A^T without doing the normalization $x^T y = 1$

process. In addition, if A is a symmetric matrix, then x is also a Perron vector of A^T and thus

$$\ell(A) = \left[\min_{1 \leq i, j \leq n} \frac{x_i}{x_j} \right]^2.$$

Example 3. Using MATLAB the spectral radius and the Perron vector x of M_2 are respectively $r(M_2) = 23.3522$ and

$$x = (0.2744, 0.3686, 0.1265, 0.1148, 0.1530, 0.1284, 0.1061, 0.2533, 0.1371, 0.2187, 0.3311, 0.1115, 0.0997, 0.1802, 0.3075, 0.4013, 0.2871, 0.0869, 0.0953, 0.2422)^T$$

Since M_2 is symmetric, that is, $M_2^T = M_2$, $y = x$ and thus $\ell(M_2) = (\min x_i / \max x_j)^2 = (0.0869/0.4013)^2 \approx 0.0469$ which matches Figure 2.

The limit in (3.1) may not exist if A is imprimitive, for example, when $A = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$, $A^{2k} = I_2$ and $A^{2k+1} = A$ for all $k = 1, 2, \dots$

4. The largest possible case $\ell(A) = 1$

When will the upper bound 1 for $\ell(A)$ be attained? A simple example is

$$J_n = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \cdots & \cdots & \cdots & \cdots \\ 1 & 1 & \cdots & 1 \end{pmatrix} \in \mathbf{N}_n,$$

that is, a matrix of all ones, since $J_n^m = n^{m-1} J_n$. Notice that the row sum and column sum of J_n are identical. The following theorem covers this very special example.

Theorem 4. *Let $A \in \mathbf{N}_n$. Then $\ell(A) = 1$ if and only if A is primitive and the row sums and column sums of A are all identical.*

Proof: Suppose A is primitive and the row sums and column sums of A are identical to ξ . In other words, A is a positive multiple of a doubly stochastic D and primitive, say $A = \xi D$. A doubly stochastic matrix is a square nonnegative matrices whose column sums and row sums are all 1. It is known that $r(D) = 1$ and thus $r(A) = \xi$. The vector $e = (1, \dots, 1)^T$ is a Perron vector for both A and A^T . In other words, $x = y = e$, and hence $\ell(A) = 1$ by (??).

On the other hand, if $A \in \mathbf{N}_n$ is primitive with $\ell(A) = 1$, then by (3.1) one concludes immediately that x and y are multiples of e and thus $Ae = A^T e = \xi e$ for some positive constant ξ . In other words, the row sums and column sums of A are all identical.

Example 5. The matrix $A = J_n - I_n \in \mathbf{N}_n$, $n \geq 3$, is primitive since $A^2 = J_n^2 - 2J_n + I_n = (n-2)J_n + I_n > 0$. So A is primitive. Clearly A has identical row sums and column sums, namely, $n-1$.

5. Biological Interpretation

Our results show bias (inverse spread < 1.0) in amino acid states early in an evolutionary process, resulting from differences in the number of evolutionary pathways leading to different amino acid states. These biases come to an equilibrium rapidly, except with respect to purifying selection. The inability to achieve certain amino acid states in the first few generations predisposes evolutionary trajectories, and is particularly important as the first generations following a significant evolutionary event, for example a gene duplication or species hybridization event, are the most significant to evolutionary outcomes [7, 8].

The inverse spread of the M_1 matrix rapidly reaches 1.0, all codon states being equally likely after a few generations. However, the genetic code is degenerate, as modeled in G_2 , resulting in more pathways to multiply-coded than singly coded amino acids. Over time (iterations) the initial inverse spread in the M_2 A -zero matrix is reduced four-fold, revealing the surprising result that degeneracy exacerbates the problem of intermediates - as the inverse spread decreases the relative number of pathways available to reach certain amino acid identities decreases, as does the relative likelihood that a path can be found that does not contain a maladaptive intermediate.

This contrasts with the results obtained when selection is considered, using transition likelihood's obtained from real proteins under purifying selection (G_3) and positive selection (G_4). Each of these modes of selection reduces the initial bias in codon states in their respective A -zero matrices, which has the paradoxical effect of increasing the likelihood of arrival of functionally unfavorable states over the course of evolution, mollifying the problem of intermediates. Under purifying selection equilibrium is not arrived at until 2000 generations have passed; in contrast to the other analysis, the effects of purifying selection on amino acid states persist over long periods of time.

The M_3 and M_4 matrices model general cases of evolution based on observed frequencies of amino acid transitions. These values are not fixed, but vary from protein to protein, such that other cases are of interest.

The case $\ell(A) = 0$ is of interest. In a given protein it is possible, even likely, that some transitions are not viable due to a specific constraint on the function of that amino acid in the protein. This results in a zero entry for that transition in the matrix. Zeros tend to propagate in a matrix over time, constraint in evolutionary pathways begets constraint, potentially resulting in the $\ell(A) = 0$ case, in which no evolution is possible. This stasis would be maintained until a change in the local environment in which the protein functions, resulting in a corresponding change in protein function and transition probabilities in the matrix, freeing the protein to evolve.

The case $\ell(A) = 1$ is also of interest. This result, obtained in our nucleotide matrix, states that all codon states are equally likely. In a biological sense, the initial bias in codon states (ie. only 8 of the 63 non-identical codons can be reached in a single step/generation) quickly disappears. This has the effect that functional considerations are free to shape codon identity without fighting any added pressures based in coding bias. We can determine ahead of time whether this is the case because of Theorem 4.

In future work, we will assess the potential impact of pathway bias by comparing amino acid transitions in real proteins sharing recent ancestors.
